University Museum, University of Pennsylvania
33rd and Spruce Streets
Philadelphia 4, Pennsylvania

Dear Beth,

Followin g our conversation of last week in Palo Alto, I ran off some total field and gradient calculations for that open shaft prospect in Egypt. The model corresponds to your sketch, except that it is 2 dimensional (infinitely extended in the y direction). This should not be too serious a drawback however, as the profiles approximate quite well a profile run over the cenetr of the shaft. I assumed the brick anomaly was induced, with a susceptibility of 4.0×10^{-3} emu, the shaft was taken to be 3.0×10^{-4}. The computer output included should be self explanatory. Note that the edge of the brick mass has a slight tendency to obscure the shaft anomaly. You might be well advised to employ a closer spaced horizontal gradient configuration, since from figure 2 the gradient curve for the brick+shaft is sharply differentiated form the brick alone gradient. For this configuration, there is a gradient cross-over, and the gradient anomaly due to the shaft is broader than the sharply rising gradient due to the edge of the brick mass. since depth to top is greater

I've included the computer output, so that you can investigate cases where the magnetic total field vector is not parallel to the strike of the brick mass (as plotted in figures 1 and 2)

Thanks for the bourbon, Frank and I ploished it off last night.

Sincerely,

Dany

Miss E. RALPH
University Museum
University of Pennsylvania
PHILADELPHIA / PENN.

Dear Miss Ralph,

Thank you for your letter enquiring about our work in Egypt. I have asked Ing. Linington and he reports that the work at Memphis seemed to show that structures of mud brick would probably give fairly large anomalies if buried in fairly pure sand. Of course if the deposits are more mixed the results will be less clear. For sites such as Memphis there seems to be little hope of gaining any useful results due to the very great complexity of the deposits.

I am glad to be able to take this opportunity to send you my best wishes for Christmas and the New Year and also those from everyone else here at Rome. In particular we hope that you are now feeling better.

With all best regards,

Lerici

(ing. Carlo M. Lerici)

Mesures et interprétation en prospection geophysique des sites archeologiques du Nil

Les conclusions exposées ici sont déduites de l'expérience de deux campagnes de prospection sur le site de Mirgissa en Nubie soudanaise (Missions 1965-66 et 1966-67)[1]. L'objectif principal de ce travail était la détection des vestiges ensablés qui risquaient de rester ignorés lors du recouvrement des lieux par les eaux du barrage d'Assouan.

De fait, si ce but a été partiellement atteint par les mesures magnétiques (découverte d'une dizaine de petites structures isolées et d'anciennes lignes de rivage), les grands murs d'enceinte, spécialement recherchés, n'ont pu être retrouvés, leurs vestiges ayant vraisemblablement disparu en plusieurs endroits. La prospection géophysique a cependant apporté une autre contribution à la recherche archéologique en permettant, toujours par la méthode magnétique, la détermination, avant fouille, d'éléments du plan d'une partie de la ville, de la forteresse et d'une autre agglomération du Moyen Empire[2]; des sondages électriques enfin ont contribué à l'établissement d'une hypothèse sur les modifications de la rive du Nil et du paysage depuis l'époque égyptienne.

Les résultats seront exposés en détail dans la publication du site de Mirgissa. L'objet, essentiellement pratique, de cet article est de préciser les conditions d'exécution des mesures, quelques solutions techniques adoptées et le mode d'interprétation des résultats.

Prospection magnétique

Le choix de ce procédé[3] était fondé sur l'observation d'un contraste de susceptibilité magnétique très élevé entre les matériaux en présence[4].

Matériaux	Susceptibilités massiques $\chi \cdot 10^6$ u.e.m. C.G.S.
sable éolien (3 éch.)	3 - 6 - 20
briques crues, mortiers (4 éch.)	295 - 254 - 240 - 100
limons et sables du Nil (3 éch.)	375 - 375 - 100

1 Je remercie particulièrement ici le Professeur Vercoutter et A. Vila pour leurs fructueux conseils, la Mission Archéologique Française qui a assuré mon séjour sur place et le Centre National de la Recherche Scientifique qui a subventionné à deux reprises mon déplacement.

2 J. Vercoutter, Excavations at Mirgissa I, Kush, vol. XII, pp. 57-62, 1964. J. Vercoutter, Nouvelles fouilles de Mirgissa, Bul. Soc. Franç. Egyptologie, n. 40, Juillet 1964.

3 Rappelons qu'il consiste en la détermination d'anomalies du champ magnétique terrestre perturbé par les structures contenues dans le sous-sol. Pour plus de détails on pourra consulter: M. J. Aitken, Physics and Archaeology, Interscience Publishers, 1961. A. Hesse, Prospections Géophysiques à faible profondeur, Applications à l'Archéologie, Dunod, 1966.

4 Je suis redevable à H. Elhaï, Maître de Conférences, d'avoir bien voulu me donner quelques uns de ses échantillons prélevés lors d'une mission précédente, et au Professeur Thellier qui s'est chargé de la détermination de leur susceptibilité magnétique (Observatoire de Physique du Globe de Saint-Maur - Seine).

Le sable éolien de provenance occidentale possède une susceptibilité magnétique extrèmement faible; de cette propriété, jointe à l'absense de sol (pl. VIII), il résulte que le gradient de champ au voisinage de la surface est très atténué. De la sorte, il était possible, dans certains cas, de poser directement la sonde du magnétomètre sur la surface à étudier et d'augmenter ainsi sensiblement la précision des localisations et la profondeur d'investigation.

Par ailleurs, les maisons sont constituées de briques crues dont le caractère magnétique est très affirmé. D'après Hoarau de la Source [5], ce sédiment contient 9,1% d'oxyde ferrique. Les autres minéraux ayant une susceptibilité négligeable, la valeur obtenue pour le sédiment brut (375.10^{-6} u.e.m. C.G.S.) révèle une certaine proportion de Fe_2O_3 γ cubique (environ 1,2% de l'ensemble du sédiment pour 7,9% de Fe_2O_3 α rhomboédrique si l'on admet des susceptibilités massiques de l'ordre de 32000.10^{-6} u.e.m. C.G.S. pour le premier (maghémite) et 20.10^{-6} u.e.m. C.G.S. pour le second (hématite) [6].

Les matériaux de construction ont une susceptibilité légèrement plus faible que le sédiment brut, qui s'explique par l'adjonction d'une certaine quantité de sable pour la préparation du mélange mis à sécher, dans le but vraisemblable d'éviter les fissures. On admettra $\chi = 250.10^{-6}$ u.e.m. C.G.S., en moyenne, dans la suite de l'exposé, soit $k = 400.10^{-6}$ u.e.m C.G.S. pour une densité des briques voisine de 1,6. Ces facteurs sont très favorables à la prospection, malgré quelques particularités inhérentes à l'appareil de mesure et à la latitude géomagnétique.

L'instrument utilisé était le magnétomètre à protons Elsec de la firme anglaise Littlemore Scientific Engineering [7]. Robuste et simple d'emploi, il a donné entière satisfaction pendant tout le temps des deux campagnes, la recharge des batteries étant effectuée chaque jour sur celles des véhicules de la Mission, en l'absence de toute autre source de courant disponible. Seule gêne, la chaleur locale, en provoquant le déclenchement intempestif de la mesure, donnait des lectures aberrantes et obligeait à travailler aux heures fraîches de la journée. Un bon isolement thermique et un étui de couleur claire suffiraient à accroître très sensiblement le temps de travail [8].

Si nous abordons les effets de la latitude géomagnétique, la faiblesse de certaines anomalies par rapport à celles observées en Europe est en partie compensée par l'augmentation de la sensibilité du magnétomètre. A Mirgissa (22° N, 31° E) les éléments du champ magnétique sont les suivants [9].

Latitude géomagnétique $\varphi = 19°$ N

L'inclinaison peut être déterminée soit par la relation:

$tg\ I = 2\ tg\ \varphi$ d'où $I = 34°\ 30'$,

soit par le rapport:

$$tg\ I = \frac{Z}{H} \text{ d'où } I = 26°\ 55\ ;$$

la valeur moyenne $I = 30°$ a été adoptée pour l'établissement des abaques.

Valeur du champ total = 0,38 oersted

Valeur absolue d'une unité magnétométrique Elsec = 0,62 γ (cette unité vaut environ 1 γ à la latitude de l'Europe).

Les caractères principaux des anomalies et leur ordre de grandeur avaient été déterminés préalablement au Centre de Recherches Géophysiques de Garchy (Nièvre) par une méthode d'intégration optique sur un principe dérivé de celui de l'abaque à mailles [10].

En effet, le mode d'interprétation simple proposé par R. E. Linington [11] en assimilant les anomalies à une fonction inverse du carré de la distance pour les structures longues, n'est pas valable entre 50° d'inclinaison et le voisinage de l'équateur magnétique. L'utilisation de modèle réduits [12] n'est possible que si la prospection a lieu dans une région magnétiquement proche de celle où se trouve l'appareil expérimental. Quant au calcul des anomalies à partir des données de Vacquier [13] ou de Aubert [14], il nous a paru moins simple que l'usage de l'intégrateur optique qui donne directement des tracés d'anomalies pour l'inclinaison choisie et l'angle de la structure avec le Nord magnétique $(0 < \theta < \frac{\pi}{2})$ (fig. 33).

Les anomalies obtenues dans le cas considéré (structu-

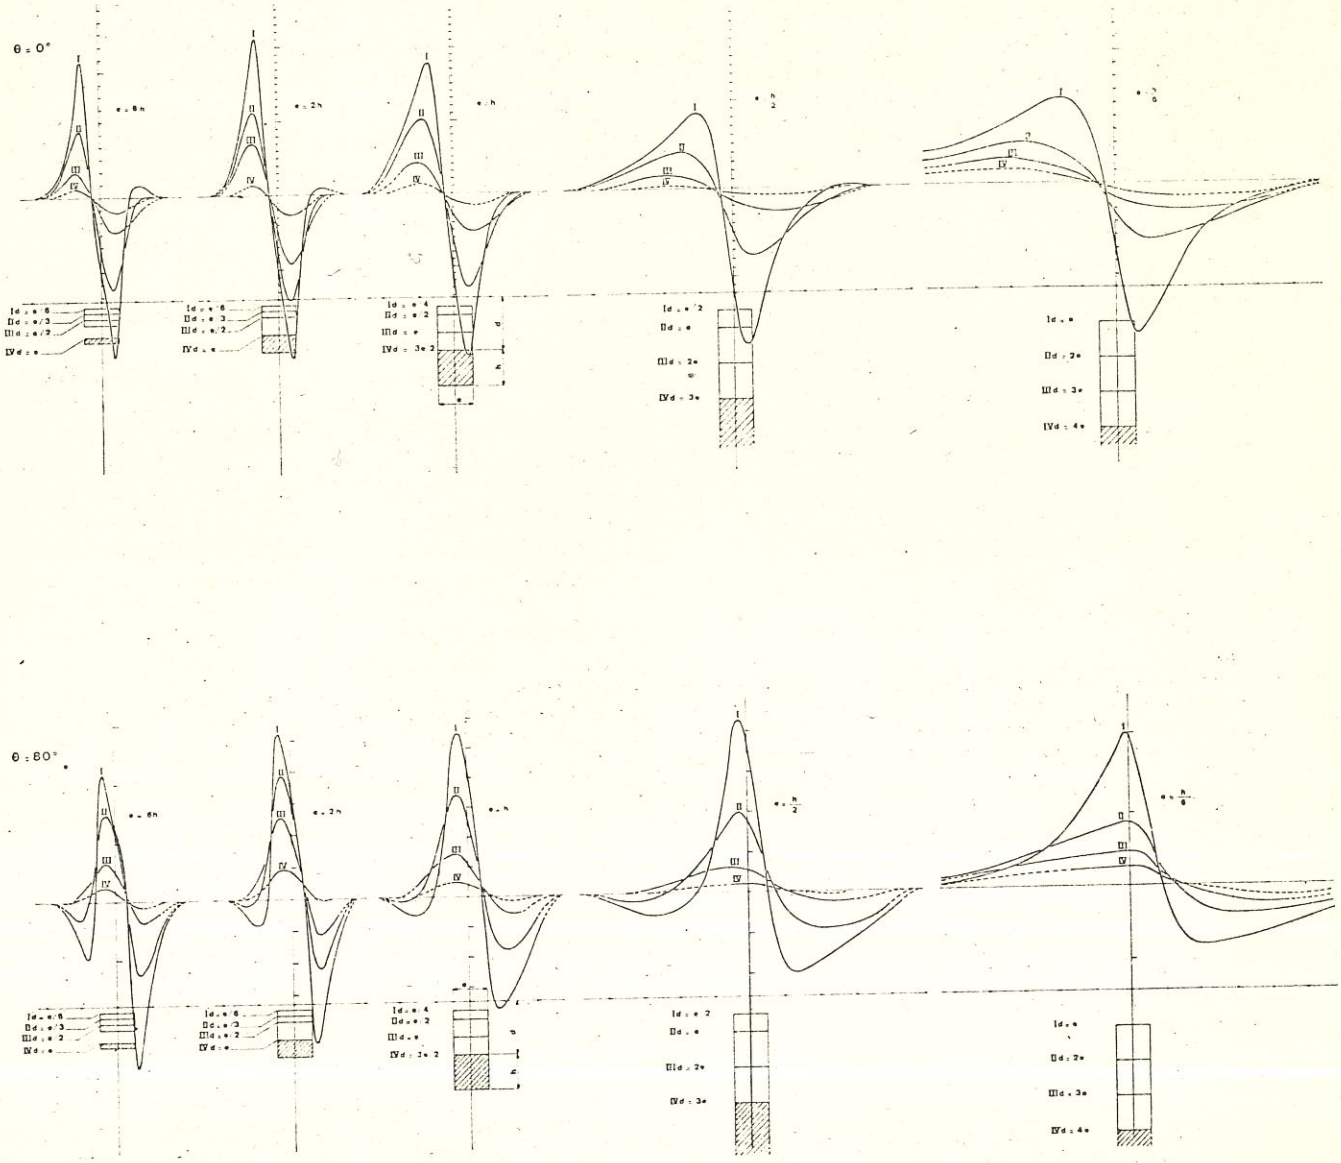

Fig. 33
Anomalies du champ magnétique total (I = 30°) provoquées par des structures longues d'axe horizontal perpendiculaire au plan de figure, et de section rectangulaire (largeur e, hauteur h) situées à la profondeur d sous la surface du sol. En abcisses, les distances des stations à l'axe sont rapportées à la longueur e. En ordonnées l'unité représente 1 γ à Mirgissa (F = 0,38 oersted, k = 400 $\times$ 10^{-6} u.e.m. C.G.S.).
Les deux séries relatives à $\vartheta = 0°$ et $\vartheta = 80°$ (ϑ : angle entre l'axe de la structure et la direction du Nord magnétique) ont seules été représentées. Les caractères intéressants des séries intermédiaires et de la série $\vartheta = 90°$ pour laquelle l'anomalie présente une symétrie, peuvent être déduits, aux détails de forme près, de la figure 3. Chaque série est subdivisible en familles suivant la hauteur de la structure (h/e croit de gauche à droite de la planche). L'aire hachurée figure la structure à la profondeur extrême étudiée; en clair le sommet des positions moins profondes. L'intervalle de variation des paramètres étant limité par les caractéristiques de l'intégrateur optique, les portions de courbe en tracé interrompu sont d'une précision incertaine.

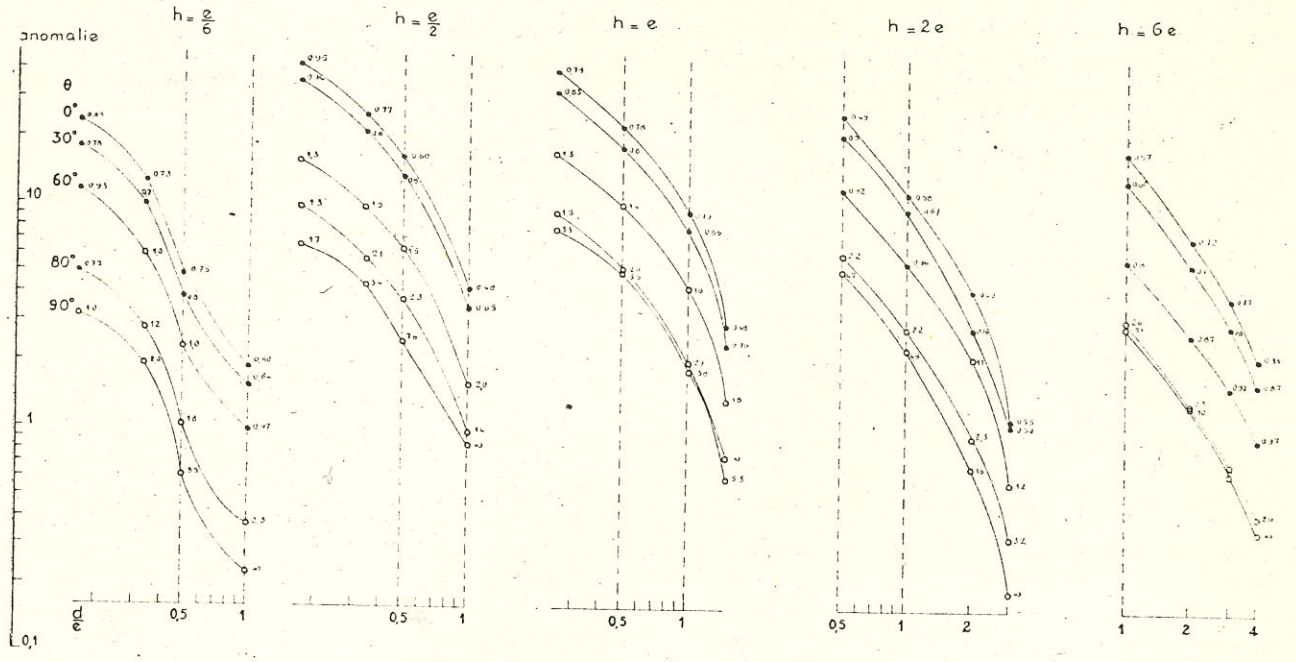

Fig. 34
Abaque des grandeurs d'anomalies du champ magnétique total (I = 30°). Pour cinq séries de valeurs de ϑ et par famille de h/e croissant de gauche à droite sont portées en ordonnées l'écart (en γ à Mirgissa) entre le sommet de l'anomalie normale et le minimum de la plus grande anomalie associée, en fonction de d/e. En regard de chaque point est indiqué le rapport des valeurs absolues de chacune de ces deux anomalies (points noirs: $\frac{\text{normale}}{\text{associée}} < 1$, points clairs $\frac{\text{normale}}{\text{associée}} > 1$).

res cylindriques horizontales à section rectangulaire, simulant des murs) présentent quelques aspects remarquables:

a. L'anomalie associée (minimum de champ au Nord de la structure) est supérieure dans certains cas à l'anomalie normale (maximum au Sud). Ce phénomène qui n'est pas observé sous nos latitudes est probablement du au fait qu'il s'agit d'anomalies du champ total. Il est particulièrement marqué pour les valeurs de θ comprises entre 0 et 45° et apparaît dans tous les cas de section rectangulaire étudiés (fig. 34).

b. Les anomalies des structures pour lesquelles θ est voisin de 90° (murs Nord-Sud) sont beaucoup plus faibles que pour θ voisin de 0° (murs Est-Ouest) (fig. 35). Ceci ne se produit pratiquement pas à la latitude de l'Europe et s'est révélé très gênant pour l'étude des constructions sur plan rectangulaire, car, en exceptant le cas où l'orientation générale est à 45° du Nord magnétique, les murs voisins de la direction Nord-Sud ne sont pratiquement pas visibles.

L'interprétation des mesures réalisées à Mirgissa n'utilise, en fait ces données que dans le cas très particulier des anomalies bien isolées de tout voisinage perturbé. La plupart du temps, les débris des contructions forment, en mélange avec le sable apporté par le vent, un remplissage complexe. L'interprétation quantitative, rendue de ce fait aléatoire et, de plus, très longue s'il fallait l'appliquer à toutes les perturbations du champ observées sur les zones construites, est remplacée par une estimation globale de la validité de l'anomalie, de la longueur et de l'orientation du mur.

Les résultats archéologiques obtenus en procédant ainsi se sont révélés très satisfaisants: identification de fours, délimitation de sous ensembles architecturaux séparés par des rues, dont l'exposé est destiné à la publication définitive.

Mesures électriques

En ce domaine, les essais ont été limités à l'exécution de sondages électriques. La prospection proprement dite est en effet très délicate compte tenu de la difficulté d'obtenir des contacts satisfaisants entre les électrodes et le sable; de plus le sens du contraste de résistivité entre les matériaux est souvent incertain, ce caractère dépendant dans une très large me-

sure de faibles variations de la teneur en eau du sable et du limon.

Les sédiments, souvent très secs, sont naturellement très résistants et le matériel utilisé (un ampéremètre Métrix permettant la lecture jusqu'à 10 μ A, un électromètre Keithley, et 500 V sur piles sèches) n'a pas permis une grande précision dans la détermination des résistivités superficielles surtout: des effets électrostatiques et ioniques, l'influence du vent sur les conducteurs rendaient les mesures difficilement reproductibles; l'abondance enfin d'un arrosage indispensable perturbait manifestement le milieu à mesurer lui-même, pour les plus petits quadripôles de chaque sondage (A B $\geq$ 3 m). De ce fait, la résistivité des sables secs superficiels a seulement pu être estimée à une valeur comprise entre 1.000 et 100.000 (Ωm)

En fixant en quelques endroits du site la profondeur du socle rocheux, qui semble s'enfoncer lentement du Nord vers le Sud, ces sondages ont cependant permis de comprendre comment la rive du Nil avait pu avancer par comblement progressif d'une partie des rapides de la Deuxième Cataracte.

Un détail opératoire peut être précisé: pour l'envoi de courant, les habituels piquets métalliques ont été remplacés par des bidons percés de nombreux petits trous, remplis de sable et copieusement arrosés par l'intérieur. Cet arrosage très efficace augmente sensiblement, et rapidement, l'intensité du courant traversant le sol pour une même tension sur les électrodes. On constate qu'à cette rapide amélioration de la résistance de contact succède une lente évolution de plusieurs heures dans le sens favorable. L'augmentation de l'intensité disponible peut aller jusqu'à décupler la valeur atteinte aussitôt après l'apport d'eau. Cet effet est intéressant car l'arrosage de l'emplacement des électrodes une journée à l'avance, permet alors des mesures assez confortables.

Plusieurs phénomènes peuvent être invoqués pour expliquer cet effet: augmentation du rayon de l'électrode par diffusion de l'eau, rôle des solutions ioniques. Des essais de laboratoire sur de petites électrodes semblables tendent à prouver que le rôle de la diffusion dans le sable est limité au temps nécessaire à l'établissement de la première amélioration de la résistance de contact. En revanche, l'importance du rôle de la mise en solution des ions est attestée par le fait qu'une solution saturée en sulfate de cuivre donne une évolution ultérieure minime (fig. 36). Dans le cas d'une argile naturelle très humide où les solutions du sol sont déjà saturées, on peut faire une épreuve inverse en apportant, toujours par l'intérieur de l'électrode, une eau peu chargée en ions: celle-ci provoque une augmentation de la résistance de contact puis un retour lent à la valeur normale. A la longue, l'électrode revient évidemment toujours à l'état initial, soit par dilution progressive des solutions l'une dans l'autre, soit par dessication dans le cas des terrains secs.

La liste des phénomènes jouant un rôle dans la dimi-

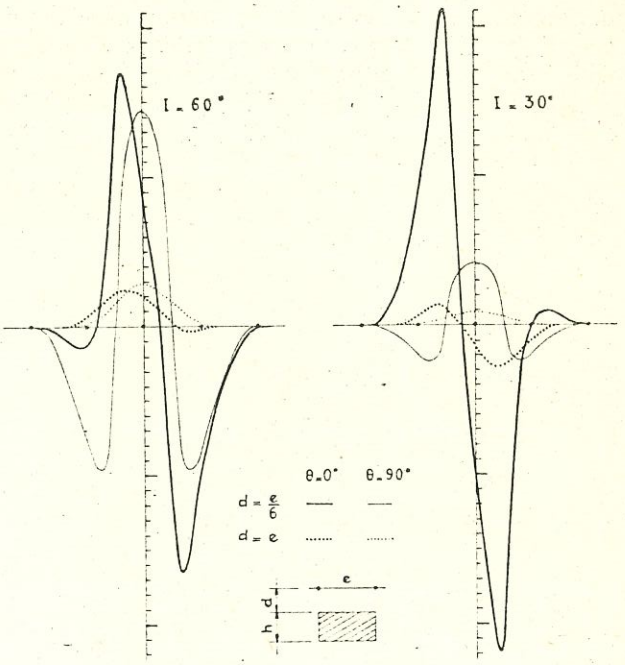

Fig. 35
Comparaison entre les effets d'une même structure à des latitudes différentes
(I = 30° : F = 0,38 oersted,
I = 60° : F = 0,46 oersted)
pour une même susceptibilité magnétique
(k = 400.10⁻⁶ u.e.m. C.G.S.).
Dans les deux cas l'unité en ordonnée vaut 1 γ.
On peut voir l'atténuation considérable provoquée par la faible latitude géomagnétique sur les structures Nord-Sud.

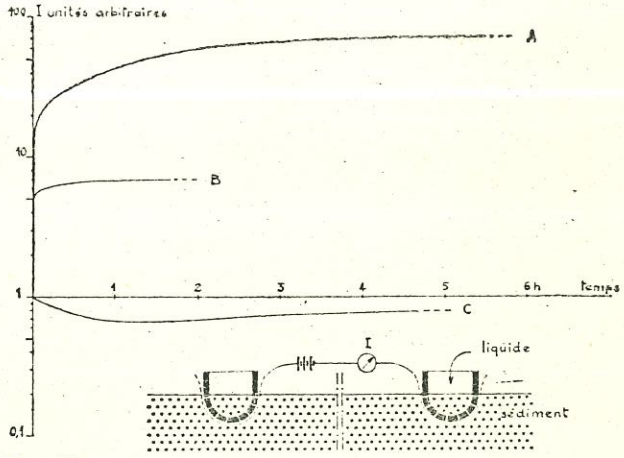

Fig. 36
Variation de l'intensité traversant une électrode métallique (fin grillage de laiton appliqué sur une hémisphère de matière plastique percée) après arrosage, dans différents sédiments
(A = eau naturelle dans sable sec,
B = eau saturée en sulfate de cuivre dans sable sec,
C = eau naturelle dans argile saturée).
Dans les trois cas, la variation en ordonnées logarithmiques, a été ramenée arbitrairement à une même intensité initiale.
L'importance de la variation secondaire de l'intensité apparaît dans le premier cas.

nution lente de la résistance de contact n'est certainement pas close par ces deux hypothèses. Quoiqu'il en soit, il peut être utile de penser à la possibilité de l'arrosage anticipé si l'on ne dispose pas de solutions salines pour l'étude par mesures électriques des sables secs.

Riassunto

L'autore espone le conclusioni raggiunte nel corso di due campagne svolte negli anni 1965-66 e 1966-67 a Mirgissa nella Nubia Sudanese, dove ha lavorato con una Missione Archeologica Francese, allo scopo di individuare le formazioni insabbiate nella zona che verrà allagata con il completamento della diga di Assuan.

La prospezione geofisica è stata molto utile per ottenere delle indicazioni sulla pianta della città, su una fortezza, su una serie di costruzioni del Medio Impero e per ipotizzare le variazioni della riva del Nilo e del paesaggio dal periodo egiziano in poi, mentre non è stata utile per trovare le grandi mura di cinta, forse distrutte in molti punti. In questo articolo l'autore espone le condizioni in cui sono state fatte le misure, le soluzioni tecniche adottate e il modo di interpretazione dei risultati seguito.

Prospezioni magnetiche

E' stato scelto questo metodo data l'esistenza di un contrasto nella suscettività magnetica della sabbia eolica che copre le formazioni archeologiche e le formazioni archeologiche stesse formate da costruzioni in mattoni crudi (vedi tabella a pag. 43 e tav. VIII). E' stato usato il magnetometro a protoni Elsec della Littlemore Scientific Engineering, che non ha mai dato alcuna preoccupazione tranne che per la mancanza di un buon isolamento termico.

Data la latitudine geomagnetica della zona (22° N, 31 E; $\varphi = 19°$ N), a Mirgissa si sono avute delle anomalie minori di quelle osservabili in Europa; questo fatto è stato peró in parte compensato dall'aumento nella sensibilità del magnetometro. Il tipo delle anomalie e il loro ordine di grandezza, era stato sperimentalmente definito in laboratorio con un metodo di integrazione ottica che dà direttamente dei profili di anomalie per l'inclinazione e la direzione delle formazioni rispetto al nord magnetico date (fig. 33). Le anomalie cosí ottenute mostrano alcune particolarità; l'anomalia associata in certi casi è superiore all'anomalia normale, probabilmente perché si tratta di anomalie del campo totale (fig. 34), e le anomalie corrispondenti a formazioni per le quali ϑ ha un valore di circa 90° (mura in direzione nord-sud), sono molto più deboli di quelle di formazioni per le quali ϑ è di circa 0° (cioè mura in direzione est-ovest) (fig. 35). Questo fenomeno ha intralciato l'individuazione di costruzioni a pianta rettangolare, perché le mura in direzione nord-sud in pratica non vengono individuate. A Mirgissa questi dati per l'interpretazione delle anomalie sono stati usati solo in casi molto semplici; per lo piú l'interpretazione è stata invece fatta in via generale stabilendo solo la lunghezza e la direzione delle mura; su questa base si sono avuti risultati archeologici soddisfacenti.

Misure elettriche

Ci si è limitati a fare alcuni sondaggi verticali, essendo una vera prospezione elettrica resa difficile dalla bassa conduttività della sabbia. La strumentazione usata (un amperometro Métrix che dà letture fino a 10 μ A, un elettrometro Keithley e delle pile a secco per 500 V) non ha permesso la determinazione esatta delle resistività superficiali; si è potuto solo approssimativamente stabilire la resistività della sabbia asciutta superficiale (da 1.000 a 100.000 (Ωm). Per trasmettere la corrente nel terreno, al posto degli elettrodi, sono stati usati dei bidoni con il fondo forato pieni di sabbia abbondantemente bagnata 24 ore prima in modo da aumentare l'intensità della corrente che attraversa il suolo (fig. 36). In questo modo si sono avute delle misure interessanti che hanno permesso di stabilire la profondità dello strato roccioso; si è potuto così dimostrare che la riva del Nilo era avanzata per il riempimento progressivo di una parte della rapida della Seconda Cataratta.
